Abstract

We survey the literature on methods for inference and learning in Bayesian Networks composed of discrete and continuous nodes, in which the continuous nodes have a multivariate Gaussian distribution, whose mean and variance depend on the values of the discrete nodes. We also briefly consider hybrid Dynamic Bayesian Networks, an extension of switching Kalman filters. This report is meant to summarize what is known at a sufficient level of detail to enable someone to implement the algorithms, but without dwelling on formalities.\(^1\)

1 Introduction

We discuss Bayesian networks (BNs [Jen96]) in which each node is either discrete or continuous, scalar or vector-valued, and in which the joint distribution over all the nodes is Conditional Gaussian (CG) [LW99, Lau92] i.e., for each instantiation \(i\) of the discrete nodes \(Y\), the distribution over the continuous nodes \(X\) has the form \(f(x|Y = i) = N(x, \mu(i), \Sigma(i))\), where \(N()\) represents a multivariate Gaussian (MVG) or Normal density. (Note that discrete nodes cannot have continuous parents in this model.) This is the most general kind of BN for which exact inference algorithms are known. A related review article is [RG97].

We start by discussing how to represent the conditional probability distribution of each node, and the joint distribution this encodes. We then give an example of a hybrid BN before discussing inference and learning techniques.

2 Representing the local conditional probability distributions

2.1 Discrete nodes

The conditional distribution of a discrete node \(X_i\) given its parents \(\text{Pa}(X_i)\) can be specified by means of a table (called a Conditional Probability Table or CPT), whose entries are \(\theta_{ijk} = \Pr(X_i = k | \text{Pa}(X_i) = j)\). Here, \(j\) denotes the \(j\)'th possible value (instantiation) that \(\text{Pa}(X_i)\) can have. Clearly we require \(\sum_k \theta_{ijk} = 1\) for all \(i\) and \(j\).

2.2 Continuous nodes

The conditional distribution of a continuous node \(X_i\) given its parents \(\text{Pa}(X_i)\) can be specified by a Gaussian function. We shall start by assuming that \(X_i\) and its parents are real valued scalars; then we shall consider the vector case, and finally the case where some of the parents are discrete.

2.2.1 Scalar case

Let node \(X_i\) have parents \(X_{k_1}, \ldots, X_{k_p}\). Then its conditional distribution is

\[
    f(x_i|x_{k_1}, \ldots, x_{k_p}) = (2\pi\sigma^2)^{-\frac{1}{2}} \exp \left[ -\frac{1}{2\sigma^2}(x_i - u_i)^2 \right]
\]

\(^1\)This work was supported by grant number 442427-21957 awarded to Prof. Russell.
where $u_i = \mu_i + \sum_{k \in \text{Pa}(X_i)} b_{ki}(x_k - \mu_k)$, and the $b_{ki}$ are the “weights” or regression coefficients on the arcs coming into node $i$ from its parents. Equivalently, we may write

$$X_i = \mu_i + \sum_{k \in \text{Pa}(X_i)} b_{ki}(X_k - \mu_k) + \sigma_i W_i$$

where $W_i \sim N(0, 1)$ is a white noise random variable.

Alternatively, we might consider the following model in which we don’t subtract off the parents’ means:

$$X_i = \sum_{k \in \text{Pa}(X_i)} b_{ki} X_k + C_i$$

where $C_i \sim N(\mu_i, \sigma_i)$ is a colored noise term.

2.2.2 Vector case

We can imagine a simple extension to the above scheme in which each node can be a vector. In this case, the conditional distribution becomes

$$f(x_i | x_k, \ldots, x_{k_0}) = N(x_i, u_i, \Sigma_i) = (2\pi)^{-\frac{1}{2}} |\Sigma_i|^{-\frac{1}{2}} \exp \left[ -\frac{1}{2} (x_i - u_i)^T \Sigma_i^{-1} (x_i - u_i) \right]$$

where $u_i = \bar{\mu}_i + \sum_k B_{ki}(x_k - \bar{\mu}_k)$. We can view this as multivariate or generalized linear regression:

$$\mathbb{E} \mathbf{X}_i = \mathbf{u}_i = \bar{\mu}_i + \sum_k B_{ki} \mathbf{X}_k - \bar{\mu}_k$$

or

$$\mathbf{E} \mathbf{X}_i = \mathbf{u}_i = \bar{\mu}_i + \sum_k B_{ki} \mathbf{X}_k$$

For example, in Figure 1(a), we have

$$\mathbf{X}_3 = \mathbf{G} \mathbf{X}_1 + \mathbf{H} \mathbf{X}_2 + \mathbf{C}$$

where $\mathbf{C} \sim N(\bar{\mu}_c, \Sigma_c)$ and we write $G = B_{13}$ and $H = B_{23}$ to avoid a profusion of subscripts.

Note that we can expand each vector into its components, yielding the equivalent scalar network shown in Figure 1(b). However, the vector notation is more compact.

2.2.3 Discrete parent case

If node $X$ has discrete parents $Y$ and continuous parents $Z$, it has a different mean, covariance and weight matrix for every value of $Y$. That is,

$$f(x_i | y = i, z) = N(x_i, \mu_i + B_i z, \Sigma_i).$$

Note that in this case it does not make sense to subtract off the parents’ means, since they may depend on their discrete parents.
Figure 1: (a) A BN with vector-valued nodes. G and H are matrices. (b) The scalar BN corresponding to (a) in the case where $X_i \in R^2$. The solid arcs to $Z_{31}$ have coefficients which correspond to the first rows of $G$ and $H$. That is, $b_{X_{31}} = (G_{11}, G_{12}, H_{11}, H_{12})$. Similarly, the dotted arcs to $X_{32}$ have coefficients which correspond to the second rows of $G$ and $H$.

3 Characterizing the corresponding joint distribution

In the introduction we stated that, if $X$ represents all the continuous nodes and $Y$ represents all the discrete nodes, then the joint distribution on $X$ given a specific $Y_i$ is a multivariate Gaussian with parameters, $\mu(i)$ and $\Sigma(i)$. We now show how to compute these parameters as a function of the local parameters of each node.

3.1 Scalar case

We start by considering the scalar case, as in [SK89]. First we compute $\Sigma$ and then $\mu$.

Construct a diagonal matrix containing the variances of each node, $D = \text{diag}(\sigma_i^2)$, and another containing the standard deviations, $S = \text{diag}(\sigma_i)$. Also, construct a matrix $B$ in which the $i$'th column contains the weight vector for node $i$. We assume the nodes are numbered topologically, so $B$ is upper triangular. Now rewrite Equation 2 in vector form as follows:

$$X - \mu = B^T(X - \mu) + SW$$

where $W = (W_1, \ldots, W_n)$ is a vector of all the noise terms. Let $E$ be the innovations or residuals, i.e., the differences (due to noise) between the values of $X$ actually realized and those predicted by the linear model:

$$E \equiv SW = (I - B^T)(X - \mu).$$

Since $B$ is strictly upper triangular, $(I - B^T)$ is invertible, so we may write

$$X - \mu = (I - B^T)^{-1}E = U^T E = U^T S^T W$$

where we have defined $U^T \equiv (I - B^T)^{-1}$, so $U = (I - B)^{-1}$. Finally, we have

$$\Sigma = \text{Var}[X] = \text{Var}[X - \mu] = \text{Var}[U^T S^T W] = U^T S^T \text{Var}[W]SU = (U^T S^T)(SU) = U^T DU.$$
Now we compute the global mean, \( \bar{\mu} \). If we use Equation 2 (i.e., subtract off the parents’ means), \( \bar{\mu} \) is just the local means stacked together. To see this, consider the following example, where \( X_1 \) is the parent of \( X_2 \).

\[
E[X_2] = E[E[X_2|X_1]] = E[\mu_2 + b(X_1 - \mu_1)] = \mu_2
\]

If instead we use Equation 3, we need to traverse the graph in topological order to compute \( \bar{\mu} \). In our simple example we have

\[
E[X_2] = E[E[X_2|X_1]] = E[\mu_2 + b_1 X_1] = b_1 \mu_1 + \mu_2
\]

### 3.2 Vector case

In this case, \( D \) and \( S \) will be block diagonal, and \( B \) will be block upper triangular. For example, in Figure 1, we have

\[
D = \begin{pmatrix}
\Sigma_{X_1} & 0 & 0 \\
0 & \Sigma_{X_2} & 0 \\
0 & 0 & \Sigma_{X_3}
\end{pmatrix} = \begin{pmatrix}
\sigma_{X_1,X_1} & \sigma_{X_1,X_2} & 0 & 0 & 0 & 0 \\
\sigma_{X_2,X_1} & \sigma_{X_2,X_2} & 0 & 0 & 0 & 0 \\
0 & 0 & \sigma_{X_3,X_2} & \sigma_{X_3,X_3} & 0 & 0 \\
0 & 0 & 0 & \sigma_{X_3,X_3} & 0 & 0 \\
0 & 0 & 0 & 0 & \sigma_{X_3,X_3} & 0 \\
0 & 0 & 0 & 0 & 0 & \sigma_{X_3,X_3}
\end{pmatrix}
\]

where we have ordered the nodes as \( X_{11}, X_{12}, X_{21}, X_{22}, X_{31}, X_{32} \). The global matrix of weights is

\[
B = \begin{pmatrix}
0 & \cdot & G^T \\
0 & \cdot & H^T \\
0 & 0 & 0
\end{pmatrix} = \begin{pmatrix}
0 & 0 & \cdots & G_{11} & G_{21} \\
0 & 0 & \cdots & G_{12} & G_{22} \\
0 & 0 & 0 & 0 & \cdots \\
0 & 0 & 0 & 0 & \cdots \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}
\]

where \( \cdot \) represents a value that happens to be 0 (because \( X \) does not connect to \( Y \)), whereas 0 represents a value that must be 0 (because of the topological ordering).

### 3.3 Conditional independence properties of Gaussian graphical models

In this section we will show that

\[
X_i \perp X_j \mid \text{(the rest)} \iff K_{ij} = 0
\]

where \( K = \Sigma^{-1} \) is the inverse covariance matrix (also called the precision matrix) of the joint distribution, and “the rest” means all the other nodes [Whi90, Edw95].

We can represent the joint distribution over all the nodes as

\[
\phi(\mathbf{x}; p, \bar{\mu}, \Sigma) = p \times \exp\left(-\frac{1}{2}(\mathbf{x} - \bar{\mu})^T \Sigma^{-1}(\mathbf{x} - \bar{\mu})\right)
\]
where
\[ p = (2\pi)^{-|\mathbf{x}|/2} |\Sigma|^{-\frac{1}{2}} \]
is a normalizing constant to ensure \( \int \phi(\mathbf{x}; p, \mu, \Sigma) = 1 \). \( p, \mu \) and \( \Sigma \) are called the moment characteristics of the distribution.

Expanding out the quadratic form and collecting terms, we can rewrite this as follows.
\[
\phi(\mathbf{x}) = \exp \left[ g + \mathbf{x}^T \mathbf{h} - \frac{1}{2} \mathbf{x}^T \mathbf{K} \mathbf{x} \right],
\]
In exponential family terminology, \( g, \mathbf{h} \) and \( \mathbf{K} \) are called the canonical characteristics, and are related to the moment characteristics as follows:
\[
\begin{align*}
K & = \Sigma^{-1} \\
h & = \Sigma^{-1} \mu \\
g & = \log p - \frac{1}{2} \mu^T \Sigma^{-1} \mu
\end{align*}
\]
where \( |\mathbf{x}| = n \). Finally, we can write the above equation in scalar form:
\[
\phi(x) = \exp \left( g + \sum_{i=1}^{n} h_i x_i - \frac{1}{2} \sum_{i} \sum_{j} K_{ij} x_i x_j \right)
\]
Using Dawid’s theorem, which states that \( X \perp Y | Z \) if the joint density can be factored as
\[
f_{X,Y,Z}(x,y,z) = g(x,z) h(y,z)
\]
we prove Equation 5.

4 Example of hybrid DBNs: switching Kalman filters

A Dynamic Bayesian Network [DW91, Gha97] is a BN used to model a temporal stochastic process. It can be created by specifying the network (structure and parameters) for two consecutive “time slices”, and then “unrolling” it into a static network of the required size. For example, in Figure 2 we show how to represent a linear dynamical system subject to Gaussian noise.

\( \mathbf{Q}_t \) represents the hidden state of the system at time \( t \), which is assumed to evolve according to the following linear equation:
\[
\mathbf{Q}_t = F_t \mathbf{Q}_{t-1} + G_t \mathbf{W}_t
\]
where \( \mathbf{W}_t \sim N(0, I) \) is a white noise random vector whose distribution is stationary. Thus we set the parameters of \( \mathbf{Q}_t \) to be \( \bar{\mu} = \mathbf{0}, \Sigma = G_t G_t^T \) and \( B = F_t \). \( \mathbf{Y}_t \) represents the observation vector at time \( t \), which is assumed to be a linear function of the hidden state:
\[
\mathbf{Y}_t = H_t \mathbf{Q}_t + J_t \mathbf{V}_t
\]
Figure 2: (a) The Kalman Filter represented as a Dynamic Bayesian Network (DBN). The hidden state variables are $Q_t$, and the observation variables are $Y_t$. The noise terms in the state evolution and sensor models are implicit in the fact that the distributions of $Q_t|Q_{t-1}$ and $Y_t|Q_t$ are Gaussian. That is, we do not have nodes for the noise variables. If the state variables are discrete, this model is called a Hidden Markov Model (HMM). (b) A discrete node $D_t$ has been added to model a switching Kalman filter.

where $V_t \sim N(0, I)$ (and is uncorrelated with $\{W_t\}$). So we set the parameters of $Y_t$ to be $\mu = 0$, $\Sigma = H_t H_t^T$, and $B = H_t$.

The task of computing the probability of the hidden state given all the past observations, $Pr(Q_t|y_1, \ldots, y_t)$, is called filtering, and the classical algorithm for it was invented by Kalman. The task of computing the probability of the hidden state given all the observations, $Pr(Q_t|y_1, \ldots, y_n)$, is called smoothing, and the classical algorithm for it was invented by Rauch. See [BSF88, BS93] for details.

The Kalman filter was developed for tracking point-like objects, such as planes and missiles. It is reasonable to represent the state (e.g., position and velocity) of a missile with a single node, $Q_t$. However, if we want to track more complicated objects, such as people, we would like to represent the complex internal spatial structure of the object with an entire network (e.g., with one node per limb). Since $Q_t$ is a jointly Gaussian rv, it can be replaced by an entire subnetwork, which also encodes a jointly Gaussian rv. The resulting network is equivalent to the one in Figure 2(a), except that the various matrices are now sparse. However, we claim that it is easier to exploit the conditional independence assumptions (for learning and possibly for speeding up inference) if they are encoded graphically as a Bayes net, rather than encoded implicitly in a sparse matrix.

We can imagine that the dynamical system has different “modes”, which we can represent by means of a discrete variable, as shown in Figure 2(b). For example, we might have one set of parameters for when a plane is taking off, another for when it is cruising, etc. This is sometimes called a jump-linear system, and the corresponding inference algorithm is the switching Kalman filter. The state evolution equation is

$$Q_t = F[D_t]Q_{t-1} + G[D_t]W_t$$

and the sensor model equation is

$$Y_t = H[D_t]Q_t + J[D_t]V_t$$

We briefly discuss the computational issues involved in performing inference in hybrid DBNs in Section 5.2.
5 Inference

We shall discuss how to perform inference in hybrid networks using a variation of the Lauritzen and Spiegelhalter method [LS88, LW89, Lau92, Ole93, Lau96], which works on undirected trees. Similar results have been derived for directed trees [Pea88, AA96, DM95] but some of the details have still to be worked out. The algorithms for directed trees involve more complicated equations, since we must work out by hand the form of various expressions involving products and integrals of multidimensional Gaussians. In contrast, for the undirected case, it suffices to show how to perform several basic operations (multiplication, division, marginalization, evidence substitution, and initialization), and we can let the computer figure out the rest.

The simplest algorithm for hybrid networks is probably SPI [CF95]; unfortunately, it is not suitable for our purposes, since we need to compute the marginal on every family for learning, and SPI takes $N$ passes to compute $N$ marginals.

5.1 Pure Gaussian case

In the discrete case, the potential over a clique can be represented as a table. In the Gaussian case, the potential can be represented as a Gaussian function in either moment or canonical form. It turns out that some operations are easier to express in terms of canonical characteristics and others are easier to express in terms of moment characteristics. In Hugin, they use both representations and switch between them as necessary. However, this requires a matrix inversion, which is slow and can introduce loss of precision. We would therefore like to work exclusively in moment form. In what follows below, we derive the equations for the moment form, but, for completeness, also state the results in [Lau92] for the canonical case.

5.1.1 Initialization

In the Lauritzen and Spiegelhalter algorithm, each clique potential is initialized to be the product of the conditional distributions of all the nodes that have been assigned to that clique. (Each node is assigned to exactly one clique, which must contain its family.) After one forwards and one backwards pass over the tree, each clique potential will be the joint distribution over all its member variables. (Let us call these “virgin potentials”.) We are then ready to incorporate evidence.

Unfortunately, we may not be able to represent the initial potential (before the initial forwards and backwards pass over the tree) in moment form. The reason is that the mean may depend on the values of some variables which have not been assigned to the clique, e.g., if only one node has been assigned to a clique, the initial potential will be of the form $f(X|Y)$; here, the mean depends on $Y$.

There are two solutions to this. One is to work out what the virgin potentials should be by traversing the graph in topological order, c.f. [CF91]. The other is to represent the initial potentials using canonical characteristics, and then, at the end of the initial pass, compute the moment form. We adopt the latter approach.

For a vector node, the conditional distribution has the form

$$f(x|z) = c \exp \left[ -\frac{1}{2} \left( (x - \mu - B^T z)^T \Sigma^{-1} (x - \mu - B^T z) \right) \right] = \exp \left[ -\frac{1}{2} (x - z) \left( \begin{pmatrix} \Sigma^{-1} & -\Sigma^{-1} B^T \\ -B \Sigma^{-1} r & B \Sigma^{-1} B^T \end{pmatrix} \begin{pmatrix} x \\ z \end{pmatrix} \right) + (x - z) \left( \begin{pmatrix} \Sigma^{-1} \mu \\ -B \Sigma^{-1} \mu \end{pmatrix} \right) - \frac{1}{2} \mu^T \Sigma^{-1} \mu + \log c \right]$$
where \( c = (2\pi)^{-n/2} |\Sigma|^{-\frac{1}{2}} \). Hence we set the canonical characteristics to
\[
g = -\frac{1}{2}\mu^T \Sigma^{-1} \mu - \frac{n}{2} \log(2\pi) - \frac{1}{2} \log |\Sigma|
\]
\[
h = \left( \begin{array}{c} \Sigma^{-1} \mu \\ -B \Sigma^{-1} \mu \end{array} \right)
\]
\[
K = \left( \begin{array}{cc} \Sigma^{-1} & -B \Sigma^{-1} B^T \\ -B \Sigma^{-T} & B \Sigma^{-1} B^T \end{array} \right)
\]
This generalizes the result in [Lau92] to the vector case. In the scalar case, \( \Sigma^{-1} = 1/\sigma \), \( \mu = \mu \), \( B = b \) and \( n = 1 \), so the above becomes
\[
g = -\frac{\mu^2}{2\sigma} - \frac{1}{2} \log(2\pi \sigma)
\]
\[
h = \frac{\mu}{\sigma} \left( \begin{array}{c} 1 \\ -b \end{array} \right)
\]
\[
K = \frac{1}{\sigma} \left( \begin{array}{cc} 1 & -b^T \\ -b & bb^T \end{array} \right).
\]
Once we have the canonical characteristics, we can compute the initial potentials for each clique by multiplying together the potentials associated with each variable which is assigned to this clique. Unfortunately, we cannot convert these canonical characteristics to moment characteristics because \( K \) is not of full rank, and hence is not invertible. (This is easy to see in the scalar case, since \( K \) contains an outer product and hence is of rank 1.)

5.1.2 Entering evidence

If we observe that a continuous variable \( Y \) takes on a specific value \( y \), we must modify the potentials of all the cliques/separator that contain \( Y \), since their dimensionality will be reduced. Let the clique contain \( X \) and \( Y \). The new potential is
\[
\phi^*(x) = \exp[g + (x^T y^T) \left( \begin{array}{c} h_x \\ h_y \end{array} \right) - \frac{1}{2} (x^T y^T) \left( \begin{array}{cc} K_{XX} & K_{XY} \\ K_{YX} & K_{YY} \end{array} \right) \left( \begin{array}{c} x \\ y \end{array} \right)]
\]
\[
= \exp[(g + h_x^T y - \frac{1}{2} y^T K_{YY} y) + x^T (h_x - K_{XY} y) - \frac{1}{2} x^T K_{XX} x]
\]
This generalizes the equation in [Lau92] to the vector case.

We can compute the analogous result for moment characteristics as follows. We will start by just considering the quadratic form
\[
Q = (x - \mu_x', y - \mu_y') \left( \begin{array}{cc} K_{XX} & K_{XY} \\ K_{YX} & K_{YY} \end{array} \right) \left( \begin{array}{c} x - \mu_x \\ y - \mu_y \end{array} \right)
\]
Expanding out,
\[
Q = (x - \mu_x')' K_{XX} (x - \mu_x) + 2(x - \mu_x')' K_{XY} (y - \mu_y) + (y - \mu_y)' K_{YY} (y - \mu_y)
\]
\[
= x' K_{XX} x - 2x' K_{XX} \mu_x + \mu_x' K_{XX} \mu_x + 2x' K_{XY} (y - \mu_y) - 2\mu_x' K_{XY} (y - \mu_y) + (y - \mu_y)' K_{YY} (y - \mu_y)
\]
\[
= x' K_{XX} x - 2x' (K_{XX} \mu_x - K_{XY} (y - \mu_y)) + (\mu_x' K_{XX} \mu_x - 2\mu_x' K_{XY} (y - \mu_y) + (y - \mu_y)' K_{YY} (y - \mu_y))
\]
\[\overset{\text{def}}{=} x'A x - 2x'b + c
\]
Now we use the following rule, called completing the square:
\[
x^T A x - 2x^T b + c = (x - A^{-1} b)^T A (x - A^{-1} b) + c - b^T A^{-1} b
\]  

(7)
to yield $\phi^*(x) = p^* \times Q(x; \mu, \Sigma)$ where

\[
\Sigma = A^{-1} \\
\mu = A^{-1}b \\
\log p^* = \log p - \frac{1}{2} (c - b'A^{-1}b)
\]

### 5.1.3 Multiplication and division

In the discrete case, we use multiplication and division to update potentials when new evidence arrives: $\Pr_W = \Pr_W \frac{\Pr_W}{\Pr_S}$, where $S$ is a separator and $W$ is a clique. Notice that $\frac{\Pr_W}{\Pr_S} = \Pr(W|S)$, so we are really computing a conditional distribution “on the fly” and multiplying in new information.

We can define multiplication and division in the Gaussian case in terms of canonical characteristics, as follows. To multiply $\phi_1(x_1, \ldots, x_n; g_1, h_1, K_1)$ by $\phi_2(x_{n+1}, \ldots, x_{2n}; g_2, h_2, K_2)$, we extend them both to the same domain $x_1, \ldots, x_n$ by adding zeros to the appropriate dimensions, and compute

\[
(g_1, h_1, K_1) \ast (g_2, h_2, K_2) = (g_1 + g_2, h_1 + h_2, K_1 + K_2)
\]

The support of the new function is the intersection of the previous supports. Division is similar, except that we define $(\phi_1/\phi_2)(x) = 0$ if $\phi_1(x) = 0$.

For moment characteristics, we use the explicit formula for conditional Gaussians (Equations 9 and 10).

### 5.1.4 Marginalization

Let $\phi_W$ be a potential over a set $W$ of variables. We can compute the potential over a subset $V \subset W$ of variables by marginalizing, denoted $\phi_V = \sum_{W \backslash V} \phi_W$. Let

\[
y = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}, \quad h = \begin{pmatrix} h_1 \\ h_2 \end{pmatrix}, \quad K = \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix}
\]

with $y_1$ having dimension $p$ and $y_2$ having dimension $q$. It can be shown (by completing the square and using nice properties of multidimensional Gaussians) that

\[
\int \phi[ (y_1^T y_2^T)^T] dy_1 = \phi[y_2; \hat{g}, \hat{h}, \hat{K}]
\]

where

\[
\hat{g} = g + \frac{1}{2} (p \log(2\pi) - \log |K_{11}| + h_1^T K_{11}^{-1} h_1) = g + \frac{1}{2} (p \log(2\pi) + \log |K_{11}^{-1}| + h_1^T K_{11}^{-1} h_1) \\
\hat{h} = h_2 - K_{21} K_{11}^{-1} h_1 \\
\hat{K} = K_{22} - K_{21} K_{11}^{-1} K_{12}
\]

In the moment case, things are much simpler. We simply extract out the components of $\mu$ and $\Sigma$ which relate to $y_2$, and change the constant so that it normalizes the new distribution.
5.2 Hybrid case

The only change in the hybrid case is that the potential functions will now be over both continuous and discrete nodes. Essentially we have one set of canonical or moment characteristics for each value of the discrete nodes. All the operations go through as before, except for marginalization. If we marginalize out over some continuous nodes, we can proceed as in Section 5.1.4, once for each value of the discrete nodes. If we marginalize out over some discrete nodes $d$, but the mean/variance do not depend on $j$, we just sum the appropriate constants ($g$ or $p$) for each value of $d$: this is called strong marginalization. However, if the mean and variance depend on $j$, we will get a mixture of Gaussians:

$$\sum_j \phi(x, j, i) = \sum_j p \times Q(x; \mu(j, i), \Sigma(j, i))$$

This cannot be simplified any further, and must be kept as a list of terms. We would therefore like to arrange things so that we integrate out all continuous nodes before the discrete nodes on which they depend, e.g., we write $\sum_i \int f(x, \mu(i), \Sigma(i))$ rather than $\int \sum_i f(x, \mu(i), \Sigma(i))$. This can be achieved by ensuring that all the continuous nodes are eliminated before their discrete ancestors. Such a node elimination ordering is called a strong triangulation, c.f.[JJD94].

Unfortunately, in the case of hybrid DBNs, the need to eliminate all the continuous nodes before their discrete ancestors clashes with our desire to eliminate all the nodes in slice $t$ before we eliminate any in slice $t+1$. If we don’t do strong triangulation, the number of mixture components becomes exponential in the length of the sequence. The standard approach (see e.g., [TSM85, BSL93, Kim94, WH97]) is to “collapse” the mixture into $k$ components. If $k = 1$, this corresponds to computing the “weak” moments:

$$\hat{p}(i) = \sum_j p(i, j)$$
$$\hat{\mu}(i) = \sum_j \hat{\mu}(i, j) p(i, j) / \hat{p}(i)$$
$$\hat{\Sigma}(i) = \sum_j \hat{\Sigma}(i, j) p(i, j) / \hat{p}(i) + \sum_j (\hat{\mu}(i, j) - \hat{\mu}(i))^T (\hat{\mu}(i, j) - \hat{\mu}(i)) p(i, j) / \hat{p}(i)$$

These will give the “correct” mean and variance:

$$\Pr[I = i] = \hat{p}(i)$$
$$\mathbf{E}[Y[I = i]] = \mathbf{E}_{Pr[J = j|I = i]}[\mathbf{E}[Y[I, J] | J = i]] = \sum_j \hat{\mu}(i, j) Pr(J = j | I = i)$$
$$\text{Var}[Y[I = i]] = \mathbf{E} \left[ \text{Var}[Y[I, J] | J = i] \right] + \mathbf{E} \left[ \text{Var}[Y[I, J| J = i]] \right] = \mathbf{E} \hat{\Sigma}(i, j) + \mathbf{E} \left[ (\hat{\mu}(i, j) - \mathbf{E} \hat{\mu}(i, j))^T (\hat{\mu}(i, j) - \mathbf{E} \hat{\mu}(i, j)) \right]$$

Lauritzen [Lau96] shows that this is the best approximation (in the KL sense) if $k = 1$.

6 Learning

In this section, we discuss how to find the Maximum Likelihood Estimates (MLEs) of the parameters associated with each node. We assume that we have a set of $N$ training examples, where each example assigns a
value to every node in the network (this is called the fully observable case). In Section 6.2, we address the issue of what to do when the values of some variables are unknown.

If we assume the parameters of node $X_i, \Theta_i$, are independent of those of all other nodes, we can maximize the $\Theta_i$’s separately. Further, the only terms in the joint distribution that depend on $\Theta_i$ involve $X_i$ and its parents, so we just need to compute the sufficient statistics for each family.

Discrete, linear Gaussian and mixtures of linear Gaussian distributions are all in the exponential family [DeG70, Bun94, Lau96]; hence the size of the sufficient statistics we need to keep is equal to the size of the parameter vector (and independent of $N$).

### 6.1 Fully observable case

#### 6.1.1 Discrete case

If $X_i$ is a discrete variable, the parameter vector is $\Theta_i = (\theta_{ijk}) = (\Pr(X_i = k|\text{Pa}(X_i) = j))$, which is just a table of numbers. The sufficient statistics are $N_{ijk}$, the number of times the event $(X_i = k, \text{Pa}(X_i) = j)$ occurs in the training set. Since

$$\theta_{ijk} = \frac{\Pr(X_i = k, \text{Pa}(X_i) = j)}{\Pr(\text{Pa}(X_i) = j)} \approx \frac{1}{N} \frac{N_{ijk}}{N_{ij}},$$

where $N_{ij} = \sum_k N_{ijk}$, the MLE is $\hat{\theta}_{ijk} = N_{ijk}/N_{ij}$.

#### 6.1.2 Gaussian case

The approach we will adopt is to model the joint distribution over a node and its parents (forming family $X$) as a MVG, compute its sufficient statistics and then find its MLE parameters.

The sufficient statistics for an MVG after seeing $N$ examples are $s_N \equiv \sum_{l=1}^N x_l$ and $Q_N \equiv \sum_{l=1}^N x_l x_l^T$, since

$$\hat{\mu}_N = \frac{1}{N} s_N = \frac{1}{N} \sum_{l=1}^N x_l,$$

and

$$\hat{\Sigma}_N = \frac{1}{N} \sum_{l=1}^N (x_l - \hat{\mu}_N)(x_l - \hat{\mu}_N)^T$$

$$= \frac{1}{N} \left[ \left( \sum_{l=1}^N x_l x_l^T \right) - \left( \sum_{l=1}^N x_l \right) \hat{\mu}_N^T - \hat{\mu}_N \left( \sum_{l=1}^N x_l^T \right) + N \hat{\mu}_N \hat{\mu}_N^T \right]$$

$$= \frac{1}{N} Q_N - \hat{\mu}_N \hat{\mu}_N^T.$$

It is simple to update the sufficient statistics when we see the next example, $x_{N+1}$.
To compute the parameters of a node given the sufficient statistics of its family, we use linear regression as follows. Let $X_1$ represent the child and $X_2$ the parents, i.e.,

$$X = \left( \begin{array}{c} X_1 \\ X_2 \end{array} \right), \quad \mu_X = \left( \begin{array}{c} \mu_{X_1} \\ \mu_{X_2} \end{array} \right), \quad \Sigma_X = \left( \begin{array}{cc} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{array} \right)$$

Then the conditional density of $X_1$ given $X_2$ is a MVG with

$$\mu_{X_1 | X_2} = E[X_1 | X_2 = x_2] = \mu_{X_1} + \Sigma_{12} \Sigma_{22}^{-1}(x_2 - \mu_{X_2})$$  \hspace{1cm} (9)

and

$$\Sigma_{X_1 | X_2} = \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}. \hspace{1cm} (10)$$

Hence the local parameters for the node are given by

$$\begin{align*}
B &= \Sigma_{YZ} \Sigma_{ZZ}^{-1} \\
\bar{\mu} &= \bar{\mu}_Y - B \bar{\mu}_Z \\
\Sigma &= \Sigma_{YY} - B \Sigma_{ZY}
\end{align*} \hspace{1cm} (11)$$

$B$ can then be broken up into its individual blocks, one for each parent.

6.1.3 Hybrid case

In [Lau96], it is shown that the sample mean, given a discrete instantiation $i$, has a $N(\bar{\mu}(i), n(i)^{-1} \Sigma(i))$ distribution, where $n(i)$ is the number of times this discrete instantiation has been seen (we assume $n(i) > 0$). The sample covariance has a Wishart distribution, $W(\Sigma(i), n(i) - 1)$, where we assume $n(i) > 1$. The unconditional posteriors will be mixtures of Gaussians and Wisharts. Nevertheless, we can compute the MLE parameters by using the appropriate sample mean and covariance, one for each discrete case. We assume that we have seen enough samples to ensure that the sample covariance matrix is positive definite, for each discrete case. Of course, we can use priors to help overcome data sparsity; see Section 6.3.

It is not clear how the “collapsing” or weak marginalization approximations affect learning, especially in the context of DBNs where we want to use all the evidence ("future" as well as past), as is traditional in off-line learning. The approach taken in [GH96] is to maximize an exact lower bound on the likelihood, produced by considering a tractable approximation to the original structure. We are currently investigating this issue experimentally.

6.2 Partially observable case

If we do not observe the value of every node in each training case, there is no longer a closed form expression for the MLE. In this section, we investigate two methods for learning under these circumstances. Both methods make many passes over the training data, and update the parameters at the end of each pass, until they reach a local maximum in likelihood space; hence they are batch methods. However, it is easy to convert them to incremental (online) versions, which update the parameters after seeing a subset of the training set (see e.g., [NH93] for incremental EM and [BC94] for incremental gradient descent).
6.2.1 EM

The basic idea of the Expectation Maximization (EM) algorithm is to “fill in” the missing values with their expected values (expectation w.r.t. the current set of parameters), and to use these Expected Sufficient Statistics (ESS) when computing the MLE. The parameters are then set to their MLE values, and the process repeats until the likelihood stops increasing (it can be proved that EM will converge to a local maximum).

In the discrete case, the ESS are

$$\mathbb{E}[N_{ijk}] = \sum_i \Pr(X_i = k, \text{Pa}(X_i) = j | e_i) = \sum_i \frac{\Pr(X_i = k, \text{Pa}(X_i) = j | e_i)}{\Pr(e_i)}.$$

The intuitive reason we divide by $\Pr(e_i)$ is that we don’t want to pay undue attention to a particular event $(X_i = k, \text{Pa}(X_i) = j)$ that happens to be highly probable by virtue of some other parameters.

In the Gaussian case, if the posterior distribution over the family $(x, i)$ given the evidence in the $l$'th case is $\Pr(x, i | e_l) \sim N(\bar{\mu}_l(i), \Sigma_l(i))$, then the ESS are

$$\sum_i \bar{\mu}_l(i)$$

and

$$\sum_i \bar{\mu}_l(i)\bar{\mu}_l(i)' + \Sigma_l(i)$$

since $E[X_iX_j] = E[X_i]E[X_j] + \text{Cov}[X_i, X_j]$.

We now present the EM algorithm in detail.

1. Choose (random) starting values for the parameters $B, \bar{\mu}, \Sigma$ for each node. A broad covariance is a good idea, so that samples far from the mean are not assigned unduly low likelihood.

2. Repeat

   (a) Reset the ESS for each node.

   (b) Reset the log-likelihood: $L = 0$.

   (c) For each training case $e$

      i. Update the log-likelihood: $L += \log \Pr(e)$.

      ii. Compute the posterior marginal over each family given the evidence.

      iii. Update the ESS for each family.

   (d) Compute the MLE of the parameters for each family given the ESS.

3. Until $L$ converges.

Steps 2(c)i and 2(c)ii can be computed using the inference algorithms we discussed earlier.

There are many variations on EM (see e.g., [MK97]), some of which may be applicable in this context. In particular, it would be interesting to know if the simple, but powerful, speedup technique in [BKS97],
which was developed in the context of discrete Bayes nets, is useful in the present case. (This technique is as follows: if $\hat{\theta}_t$ is the vector of parameters at iteration $t$, and $\tilde{\theta}_{t+1} = U(\hat{\theta}_t)$ are the updated parameters suggested by the M step of EM, then use instead $\tilde{\theta}_{t+1} = (1 - \lambda)\hat{\theta}_t + \lambda U(\hat{\theta}_t)$ for $\lambda > 1$. This rule is somewhat counterintuitive because it involves adding a negative fraction of the old values to the new values, but can be justified both from a theoretical on-line learning perspective [BKS97] or from a more classical statistical perspective [BW84].)

6.3 Using priors to compute the MAP estimate

To avoid overfitting when we have too little training data, we can use priors, and compute the MAP estimates instead of the ML estimates. A suitable prior for discrete nodes is the Dirichlet prior, which has a simple intuitive interpretation in terms of pseudo counts: we just imagine that we have seen a certain number $N_{ijk}$ of cases of the event $(X_i = k, Pa(X_i) = k)$, and add these to our real counts. For the vector Gaussian case, things are a little more complicated. It is simpler to associate a prior with the MVG distribution $N(\mu_P, \Sigma_P)$ on the family $\mathcal{F}$, rather than with the parameters $(\mu_X, \Sigma_X, b_X)$ of the node itself. A suitable prior is the Normal-Wishart [GH94, DeG70]. This can be important since it takes a lot of data to ensure $\Sigma$ is positive definite.
